**EasyCrypt’s While Language and Hoare Logic**

These slides are an example-based introduction to the features of *EasyCrypt*’s while loop language that correspond to the language we’ve studied in class so far (and that are used in the notes by Gilles Barthe), as well as the features of *EasyCrypt*’s Hoare logic.

The *EasyCrypt* tactics for Hoare logic are motivated by the ones we’ve studied in class, but are different in some key ways.
In EasyCrypt’s while language, commands (or statements) are enclosed in procedures, which are in turn enclosed in modules. Furthermore, modules may have global variables, which their procedures may read and write.

Procedures may call other procedures. But we don’t need to make use of this feature at this point in the course. And so consequently we’ll ignore for now the Hoare logic tactics for working with procedure calls.
Here is a sample program, which we’ll use as our first running example:

```plaintext
module M = {
  var x, y : int

  proc f() : unit = {
    if (0 <= x) {
      while (0 < x) {
        x <- x - 1;
        y <- y + 1;
      }
    } else {
      while (x < 0) {
        x <- x + 1;
        y <- y - 1;
      }
    }
  }
}. 
```
**First Example Program**

In the above program, the procedure f takes in no arguments, and implicitly returns the single element (()) of type unit. Its assignments are written using <-, instead of the := notation used in class. They read and write the global variables x and y of the module M.

We can think of the integers x and y as the inputs of the program, and of y as the program’s output. It’s not hard to see that the final value of y will be equal to the sum of the original values of x and y.
Hoare Triple for Example Program

Because the variables $x$ and $y$ are modified during the running of our example program, to state the correctness of the program as a Hoare triple, we need a way of referring to the \textit{original} values of $x$ and $y$. 
Hoare Triples

Fortunately, we can do this in \texttt{EASYCRYPT} using its ambient logic:

```plaintext
lemma correct (x_ y_ : int) :
  hoare[M.f : M.x = x_ \And M.y = y_ ==> M.y = x_ + y_].
proof.
...
qed.
```

The lemma is parameterized by mathematical variables \( x_ \) and \( y_ \), which are intended to be the initial values of the program’s inputs. Its conclusion is \texttt{EASYCRYPT}'s expression of a Hoare triple. The program is \( M.f \). The precondition

\[
M.x = x_ \And M.y = y_
\]

assumes that the values of \( M.x \) and \( M.y \) are \( x_ \) and \( y_ \), respectively. And the postcondition

\[
M.y = x_ + y_
\]

requires that the final value of \( M.y \) be the sum of \( x_ \) and \( y_ \).
Proof of First Example

When we begin proving our lemma, we have the goal

Type variables: <none>

\[ x_\_ \text{:: int} \]
\[ y_\_ \text{:: int} \]

\[ \text{pre} = M.x = x_\_ \land M.y = y_\_ \]
\[ M.f \]
\[ \text{post} = M.y = x_\_ + y_\_ \]

where the conclusion is just another way of writing the same Hoare triple.

We begin by applying the tactic proc, which inlines the code of \( f \), transforming this goal into:
Proof of First Example

Type variables: <none>

x_: int
y_: int

pre = M.x = x_ /\ M.y = y_

(1----) if (0 <= M.x) {
(1.1--) while (0 < M.x) {
(1.1.1) M.x <- M.x - 1
(1.1.2) M.y <- M.y + 1
(1.1--) }
(1----) } else {
(1?1--) while (M.x < 0) {
(1?1.1) M.x <- M.x + 1
(1?1.2) M.y <- M.y - 1
(1?1--) }
(1----) }

post = M.y = x_ + y_
Proof of First Example

Because the first statement is an if, we can use the tactic if to split this goal into two subgoals, depending upon whether \( M.x \) is non-negative or not:

Type variables: <none>

\[
\begin{align*}
x_: \text{int} \\
y_: \text{int}
\end{align*}
\]

Context : {}

\[
\text{pre} = (M.x = x_ \land M.y = y_) \land 0 \leq M.x
\]

\[
(1--) \quad \text{while } (0 < M.x) \{
(1.1) \quad M.x <- M.x - 1 \\
(1.2) \quad M.y <- M.y + 1 \\
(1--) \quad \}
\]

\[
\text{post} = M.y = x_ + y_
\]

(for the “then” part) and
Proof of First Example

Type variables: <none>

x_: int
y_: int

Context : {}

pre = (M.x = x_ /\ M.y = y_) /\ ! 0 <= M.x

(1--) while (M.x < 0) {
(1.1) M.x <- M.x + 1
(1.2) M.y <- M.y - 1
(1--) }

post = M.y = x_ + y_

(for the “else” part).
Proof of First Example

With both of these subgoals, the final (only in this case) statement is a while loop, and thus we can apply the while tactic, for which we need to supply an invariant. We’ll only consider the proof of the first subgoal, the other being similar.

It’s perhaps obvious that the invariant should include that the sum of $M.x$ and $M.y$ is equal to the sum of $x_-$ and $y_-$. But we’ll also need that $0 \leq M.x$.

In the goal where $0 \leq M.x$, running

\[
\text{while (0} \leq M.x \land M.x + M.y = x_- + y_-)\).
\]

generates the two subgoals
Proof of First Example

Type variables: <none>

x_: int
y_: int

Context : {}

pre =
(0 <= M.x \(\land\) M.x + M.y = x_ + y_) \(\land\) 0 < M.x

(1) M.x <- M.x - 1
(2) M.y <- M.y + 1

post = 0 <= M.x \(\land\) M.x + M.y = x_ + y_

(showing that the body of the loop preserves the invariant when M.x is positive) and
Proof of First Example

Type variables: <none>

\[ x_\_ : \text{int} \]
\[ y_\_ : \text{int} \]

Context : {}

pre = \((M.x = x_\_ \land M.y = y_\_) \land 0 \leq M.x)\]

post =
\[
(0 \leq M.x \land M.x + M.y = x_\_ + y_\_)\]
\[
\forall (x \; y : \text{int}), \quad
!0 < x \Rightarrow
0 \leq x \land x + y = x_\_ + y_\_ \Rightarrow y = x_\_ + y_\_
\]

(connecting the while loop to the pre- and postconditions of the goal on which the while tactic was run). We’ll come back to this second subgoal; but first, let’s consider how to prove the first one.
Proof of First Example

To prove

Type variables: <none>

\[ x_\_ : \text{int} \]
\[ y_\_ : \text{int} \]

Context : {}

\[ \text{pre} = \]
\[ (0 \leq M.x \land M.x + M.y = x\_ + y\_) \land 0 < M.x \]

(1) \[ M.x <- M.x - 1 \]
(2) \[ M.y <- M.y + 1 \]

\[ \text{post} = 0 \leq M.x \land M.x + M.y = x\_ + y\_ \]

we can push the assignments at the end of the program (all of the program in this case) into the postcondition, using the tactic \( \text{wp} \), which stands for “weakest precondition”.

Proof of First Example

The \texttt{wp} tactic optionally takes an argument which (somewhat confusingly) is the number of statements at the \textit{beginning} of the program that we \textit{don’t} want \texttt{wp} to try to push into the postcondition. This version of the tactic may fail, if it’s not possible to push enough statements into the postcondition. In this example,

\begin{verbatim}
  wp 0.
\end{verbatim}

would have the same effect as \texttt{wp}.
Proof of First Example

In terms of the logic learned in class, it’s equivalent to repeated use of the rule for assignment, combined with what the slides called the Rule of Hoare Logic Composition. This results in the goal:

Type variables: <none>

x_: int
y_: int

Context : {}

pre =
   (0 <= M.x \ M.x + M.y = x_ + y_) \ 0 < M.x

post =
   let x = M.x - 1 in
   0 <= x \ x + (M.y + 1) = x_ + y_
Proof of First Example

Because the program of

Type variables: <none>

\[ \begin{align*}
  x_\_ & : \text{int} \\
  y_\_ & : \text{int}
\end{align*} \]

--------------------------------------------

Context : {}

\[ \begin{align*}
  \text{pre} & = \\
  & (0 \leq M.x \land M.x + M.y = x_\_ + y_\_) \land 0 < M.x \\
\end{align*} \]

\[ \begin{align*}
  \text{post} & = \\
  & \text{let } x = M.x - 1 \text{ in} \\
  & 0 \leq x \land x + (M.y + 1) = x_\_ + y_\_ \\
\end{align*} \]

is empty, we can use the skip tactic to reduce it to the ambient logic formula:
Proof of First Example

Type variables: <none>

\[ \begin{align*}
\text{x}_&: \text{int} \\
\text{y}_&: \text{int}
\end{align*} \]

---------------------------------------------

forall \&hr,
\[ (0 \leq M.x_{\&hr} \land M.x_{\&hr} + M.y_{\&hr} = \text{x}_ + \text{y}_) \land \]
\[ 0 < M.x_{\&hr} \Rightarrow \]
\[ \text{let } x = M.x_{\&hr} - 1 \text{ in} \]
\[ 0 \leq x \land x + (M.y_{\&hr} + 1) = \text{x}_ + \text{y}_ \]

Here \&hr stands for an arbitrary memory, and \( M.x_{\&hr} \) and \( M.y_{\&hr} \) stand for the values of \( M.x \) and \( M.y \) in that memory. As an example, we will solve this goal without using the smt tactic.
Proof of First Example

First, we introduce \&hr into the assumptions by running the tactic

\texttt{move => \&hr.}

which takes us to the goal

\begin{align*}
\text{Type variables: } & \langle \text{none} \rangle \\
x_\_: \text{int} \\
y_\_: \text{int} \\
\&hr: \{\} \\
\begin{array}{c}
(0 \leq M.x{hr} \land M.x{hr} + M.y{hr} = x_\_ + y_\_) \land \\
0 < M.x{hr} \Rightarrow \\
\text{let } x = M.x{hr} - 1 \text{ in} \\
0 \leq x \land x + (M.y{hr} + 1) = x_\_ + y_\_
\end{array}
\end{align*}
Proof of First Example

Next, we run the introduction pattern

\[
\text{move } \Rightarrow /= [] [] \text{ ge0}_M_x \text{ eq}_\text{plus} \text{ gt0}_M_x.
\]

which takes us to the goal

Type variables: <none>

\[
\begin{align*}
x_\_ & : \text{int} \\
y_\_ & : \text{int} \\
&\_r & : {} \\
ge0_M_x & : 0 \leq M.x_{\_r} \\
eq_plus & : M.x_{\_r} + M.y_{\_r} = x_\_ + y_\_ \\
gt0_M_x & : 0 < M.x_{\_r} \\
\end{align*}
\]

\[
0 \leq M.x_{\_r} - 1 \land \\
M.x_{\_r} - 1 + (M.y_{\_r} + 1) = x_\_ + y_\_
\]
Proof of First Example

Next, we apply the split tactic, which reduces the goal to two goals. The first of these is

Type variables: <none>

\[
\begin{align*}
x_\_ &: \text{int} \\y_\_ &: \text{int} \\
&hr &: \{} \\
ge0_M_x &: 0 \leq M.x_{hr} \\
eq_plus &: M.x_{hr} + M.y_{hr} = x_\_ + y_\_ \\
gt0_M_x &: 0 < M.x_{hr} \\
\end{align*}
\]

\[
\begin{align*}
0 \leq M.x_{hr} - 1 \\
\end{align*}
\]

from which we can run the tactic

\[
\text{rewrite ler_subr_addr /=.}
\]

producing the goal
Proof of First Example

Type variables: <none>

\[\begin{align*}
x_\_ & : \text{int} \\
y_\_ & : \text{int} \\
\&hr & : \{\} \\
ge0_{M_x} & : 0 \leq M.x_{hr} \\
eq_{\text{plus}} & : M.x_{hr} + M.y_{hr} = x_\_ + y_\_ \\
\gt0_{M_x} & : 0 < M.x_{hr} \\
\end{align*}\]

which we can solve by running the tactic

\[
\text{rewrite } \text{ltzE } // \text{ in } \gt0_{M_x}.
\]
Proof of First Example

And the second goal produced by split is

Type variables: <none>

\[
\begin{align*}
x_\_ : & \quad \text{int} \\
y_\_ : & \quad \text{int} \\
& \text{hr} : \{\} \\
ge0\_M\_x : & \quad 0 \leq M.x^{\text{hr}} \\
eq\_\plus : & \quad M.x^{\text{hr}} + M.y^{\text{hr}} = x_\_ + y_\_ \\
gt0\_\_M\_x : & \quad 0 < M.x^{\text{hr}} \\
\end{align*}
\]

which we can solve by running the tactic

\[
\text{by rewrite (addrC \_ 1) addrA /= eq\_plus}.
\]
Proof of First Example

Now let’s go back to the second subgoal generated by running the `while` tactic:

Type variables: <none>

\[ x_\_ : \text{int} \]

\[ y_\_ : \text{int} \]

Context : {}

\[ \text{pre} = (M.x = x_\_ \land M.y = y_\_) \land 0 \leq M.x \]

\[ \text{post} = \\
(0 \leq M.x \land M.x + M.y = x_\_ + y_\_) \land \\
\forall (x \ y : \text{int}), \\
\quad ! \ 0 < x \Rightarrow \\
\quad 0 \leq x \land x + y = x_\_ + y_\_ \Rightarrow y = x_\_ + y_\_ \]

Here there is no program, because nothing came before the while loop.
Proof of First Example

The post condition

\[(0 \leq M.x \land M.x + M.y = x_ + y_) \land \forall (x \ y : \text{int}), \]
\[! \ 0 < x \Rightarrow \]
\[0 \leq x \land x + y = x_ + y_ \Rightarrow y = x_ + y_\]

has two conjuncts.

The first is the invariant specified to the while tactic, as it must be true that when the while loop is entered, the invariant holds.
Proof of First Example

Postcondition:

\[(0 \leq M.x \land M.x + M.y = x_ + y_) \land \forall (x y : \text{int}),
   \neg 0 < x =\>
   0 \leq x \land x + y = x_ + y_ \Rightarrow y = x_ + y_\]

The second part quantifies over the values \(x\) and \(y\), representing the values of the variables modified by the while loop at the point where the loop is exited. It has implications assuming that the boolean expression of the while loop is false, and the loop’s invariant holds, and requiring us to prove that the original postcondition \((M.y = x_ + y_)\) holds—all expressed in terms of \(x\) and \(y\) instead of \(M.x\) and \(M.y\).

The combination of \(\neg 0 < x\) and \(0 \leq x\) tells us that \(x\) is zero, which is why \(y = x_ + y_\) holds, and also why \(0 \leq x\) needed to be part of the invariant.
Proof of First Example

Because the goal’s program part is empty, running `skip` reduces the goal to:

Type variables: <none>

\[ x_: \text{int} \]
\[ y_: \text{int} \]

\[
\text{forall } \&hr, \quad (M.x_{\&hr} = x_ \land M.y_{\&hr} = y_ ) \land 0 \leq M.x_{\&hr} \implies \]
\[
(0 \leq M.x_{\&hr} \land M.x_{\&hr} + M.y_{\&hr} = x_ + y_ ) \land \]
\[
\text{forall } (x \ y : \text{int}), \quad \]
\[
! 0 < x \implies \quad 0 \leq x \land x + y = x_ + y_ \implies y = x_ + y_ \]

And running `smt()` will solve this goal.
Proof of First Example

Note that only the variables *modified* by the while loop are universally quantified in the postcondition. Thus if the postcondition $\Phi$ of the goal on which the *while* tactic is run refers to variables used by the part of the program that comes before the while loop, or by the precondition of the goal on which the *while* tactic is run, whatever is known about those variables upon entry to the while loop can be used when proving $\Phi$. 
Second Example

Because procedures can take arguments and return results, here’s an alternative version of our example:

```plaintext
module M' = {
  proc f(x : int, y : int) : int = {
    var x', y' : int;
    x' <- x; y' <- y;
    if (0 <= x') {
      while (0 < x') {
        x' <- x' - 1; y' <- y' + 1;
      }
    }
    else {
      while (x' < 0) {
        x' <- x' + 1; y' <- y' - 1;
      }
    }
    return y';
  }
}
```
Second Example

Here:

- $x$ and $y$ are arguments of $f$,
- the variables manipulated by the while loops are local variables $x'$ and $y'$, and
- $y'$ is explicitly returned as the result of $f$.

This time the lemma to be proved is:

\[
\text{lemma correct'} \ (x_\, y_ \ : \ \text{int}) :
\quad \text{hoare}[M'.f : x = x_ \land y = y_ \implies \text{res} = x_ + y_].
\]

Note how the precondition refers to the values of $f'$’s arguments, and how $\text{res}$ in the postcondition is used to stand for the result returned by $f$. 
Proof of Second Example

The proof of the second example is only slightly different from that of the first one. We start with the goal

Type variables: <none>

\begin{align*}
x_ & \colon \text{int} \\
y_ & \colon \text{int} \\
\end{align*}

pre = \( x = x_ \land y = y_ \)

\( M'.f \)

post = res = x_ + y_ 

Running proc then gives us the goal
Proof of Second Example

Type variables: <none>

\[
\begin{align*}
\text{x}_{\_}: \text{int} \\
\text{y}_{\_}: \text{int}
\end{align*}
\]

Context : \{x, y, x', y' : \text{int}\}

\[\text{pre} = (x, y).'1 = x_\_ /\ (x, y).'2 = y_\_
\]

(1----) \text{x}' \leftarrow x
(2----) \text{y}' \leftarrow y
(3----) if (0 \leq \text{x}') {
(3.1--)
\text{while} (0 < \text{x}') {
(3.1.1) \text{x}' \leftarrow \text{x}' - 1
(3.1.2) \text{y}' \leftarrow \text{y}' + 1
(3.1--)
\}
(3----) } \text{else} {
(3?1--)
\text{while} (\text{x}' < 0) {
(3?1.1) \text{x}' \leftarrow \text{x}' + 1
(3?1.2) \text{y}' \leftarrow \text{y}' - 1
(3?1--)
(3----) }
\]

\[\text{post} = \text{y}' = x_\_ + y_\_\]

\[\frac{32}{65}\]
Proof of Second Example

Note that the postcondition now involves $y'$ not $\text{res}$, since $y'$ is what is returned by $f$.

The precondition involves the notation for selecting the first or second component of a pair. If we run the tactic `simplify`, we get the goal:
Proof of Second Example

Type variables: <none>

\( x_\ldots \text{int} \)
\( y_\ldots \text{int} \)

Context : \{x, y, x', y' : int\}

\( \text{pre} = x = x_\ldots \land y = y_\ldots \)

(1----) \( x' \leftarrow x \)
(2----) \( y' \leftarrow y \)
(3----) if (0 ≤ x') {
(3.1--) while (0 < x') {
(3.1.1) \( x' \leftarrow x' - 1 \)
(3.1.2) \( y' \leftarrow y' + 1 \)
(3.1--) }
(3----) } else {
(3?1--) while (x' < 0) {
(3?1.1) \( x' \leftarrow x' + 1 \)
(3?1.2) \( y' \leftarrow y' - 1 \)
(3?1--) }
(3----) }

\( \text{post} = y' = x_\ldots + y_\ldots \)
Proof of Second Example

Because the if statement is *not* the first statement of the program, we can’t directly run the if tactic. Instead we must use EasyCrypt’s sequencing tactic (based on the Rule of Hoare Logic Composition) to split this goal into one involving the first two assignments, and one involving the if statement.

We run the tactic

\[ \text{seq 2 : (} x' = x_0 /\ y' = y_0 \text{).} \]

Here the 2 is the number of statements to use for the first subgoal, and the condition will be used as the postcondition of the first subgoal, and the precondition of the second subgoal. Here are the goals we get after running this tactic:
Proof of Second Example

Type variables: <none>

\[ x_\_: \text{int} \]
\[ y_\_: \text{int} \]

Context : \{x, y, x’, y’ : \text{int}\}

\[ \text{pre} = x = x_\_ \land y = y_\_ \]

(1) \[ x’ \leftarrow x \]

(2) \[ y’ \leftarrow y \]

\[ \text{post} = x’ = x_\_ \land y’ = y_\_ \]

(which we know how to solve using \text{wp}; \text{skip}; \text{trivial}) and
Proof of Second Example

Type variables: <none>

\[
\begin{align*}
x_\_ : \text{int} \\
y_\_ : \text{int}
\end{align*}
\]

Context : \{x, y, x', y' : \text{int}\}

pre = \(x' = x_\_ \land y' = y_\_
\]

(1----) if (0 =\leq x') {
(1.1--) while (0 < x') {
(1.1.1) \quad x' \leftarrow x' - 1 \\
(1.1.2) \quad y' \leftarrow y' + 1 \\
(1.1--) }
(1----) } else {
(1?1--) while (x' < 0) {
(1?1.1) \quad x' \leftarrow x' + 1 \\
(1?1.2) \quad y' \leftarrow y' - 1 \\
(1?1--) }
(1----) }

post = \(y' = x_\_ + y_\_
\]

(which is proved just like the analogous goal of the first example).
Proof of Second Example

Here is the complete proof of the second example:

```lean
lemma correct' (x_ y_ : int) :
    hoare[M'.f : x = x_ /\ y = y_ ==> res = x_ + y_].
proof.
proc; simplify.
seq 2 : (x' = x_ /\ y' = y_).
wp; skip; trivial.
if.
while (0 <= x' /\ x' + y' = x_ + y_).
wp; skip; smt().
skip; smt().
while (x' <= 0 /\ x' + y' = x_ + y_).
wp; skip; smt().
skip; smt().
qed.
```
More on \texttt{wp} Tactic

The \texttt{wp} tactic can actually push (possibly nested) conditionals and assignment statements at the end of the program into the postcondition. E.g., if the program is

\begin{verbatim}
module L = {
  var w : int

  proc f(x y : int) : unit = {
    if (x < y) {
      w <- y - x;
    }
    else {
      w <- x - y;
    }
  }
}.
\end{verbatim}

then running

\begin{verbatim}
wp.
\end{verbatim}
More on \texttt{wp Tactic}

transforms the goal

Type variables: <none>

Context : \{x, y : \text{int}\}

pre = true

(1--) if (x < y) {
(1.1) \quad \text{L.w} \leftarrow y - x
(1--) } else {
(1?1) \quad \text{L.w} \leftarrow x - y
(1--) }

post = 0 \leq \text{L.w}

into
More on \texttt{wp} Tactic

Type variables: <none>

--------------------------------------------
Context : \{x, y : \text{int}\}

pre = true

post = if x < y then 0 \leq y - x else 0 \leq x - y
The sp Tactic

Dual to the \( \text{wp} \) tactic, there is the \( \text{sp} \) ("strongest postcondition") tactic, which can push (possibly nested) conditionals and assignment statements at the \textit{beginning} of the program into the precondition. E.g., if the program is

```plaintext
module L = {
    var w : int

    proc f(x y : int) : unit = {
        if (x < y) {
            w <- y - x;
        }
        else {
            w <- x - y;
        }
    }
}.
```

then running

```
sp.
```
The \text{sp} Tactic transforms the goal

Type variables: <none>

Context : \{x, y : \text{int}\}

type pre = true

\begin{verbatim}
(1--)
if (x < y) {
(1.1) L.w <- y - x
(1--) } else {
(1?1) L.w <- x - y
(1--) }
\end{verbatim}

post = 0 <= L.w

into
The sp Tactic

Type variables: <none>

Context : \{x, y : int\}

pre =
    L.w = y - x \land x < y \lor L.w = x - y \land \neg x < y

post = 0 \leq L.w
The \texttt{sp} Tactic

\texttt{sp} optionally takes as an argument the number of statements at the beginning of the program that \texttt{EASYCRYPT} should try to push into the precondition. This version of the tactic will fail if that action is impossible.
Finally, the auto tactic will run \texttt{wp}, and then continue with \texttt{skip}, if the program becomes empty.

E.g., if the program is

```ocaml
module L = {
  var w : int

  proc f(x y : int) : unit = {
    while (true) { }
    if (x < y) {
      w <- y - x;
    } else {
      w <- x - y;
    }
  }
}.
```

then running

```ocaml
auto.
```
The **auto Tactic** transforms the goal

Type variables: `<none>`

Context: `{x, y : int}`

pre = true

(1--) if (x < y) {
(1.1) L.w <- y - x
(1--) } else {
(1?1) L.w <- x - y
(1--) }

post = 0 <= L.w

into
**The auto Tactic**

Type variables: <none>

```
forall &hr,
  true =>
  if x{hr} < y{hr} then 0 <= y{hr} - x{hr}
  else 0 <= x{hr} - y{hr}
```

auto actually does more than just this. It's always safe to use, but may not make any progress.
The case, rcondt and rcondf Tactics

Let’s go back to a goal that we solved using the if tactic, and show how we can instead solve it using the case, rcondt and rcondf tactics.
The case, `rcondt` and `rcondf` Tactics

Type variables: <none>

\[
x_\_ : \text{int} \\
y_\_ : \text{int}
\]

Context : \{x, y, x', y' : \text{int}\}

\[
\text{pre} = x' = x \land y' = y \land x = x_\_ \land y = y_\_
\]

(1----) if (0 <= x') {
(1.1--) while (0 < x') {
(1.1.1) x' <- x' - 1
(1.1.2) y' <- y' + 1
(1.1--) }
(1----) }
(1----) } else {
(1?1--)
(1?1--) while (x' < 0) {
(1?1.1) x' <- x' + 1
(1?1.2) y' <- y' - 1
(1?1--) }
(1----) }

\[
\text{post} = y' = x_\_ + y_\_
\]
The case, rcondt and rcondf Tactics

The case tactic also works with Hoare logic goals, and running

    case (0 <= x').

gives us the goals
The case, rcondt and rcondf Tactics

Type variables: <none>

x_: int
y_: int

Context : {x, y, x’, y’ : int}

pre = (x’ = x \ y’ = y \ x = x_ \ y = y_) \ 0 <= x’

(1----) if (0 <= x’) {
(1.1--) while (0 < x’) {
(1.1.1) x’ <- x’ - 1
(1.1.2) y’ <- y’ + 1
(1.1--) }
(1----) } else {
(1?1--) while (x’ < 0) {
(1?1.1) x’ <- x’ + 1
(1?1.2) y’ <- y’ - 1
(1?1--) }
(1----) }

post = y’ = x_ + y_

and

52 / 65
The case, rcondt and rcondf Tactics

Type variables: <none>

x_: int
y_: int

Context : {x, y, x’, y’ : int}

pre = (x’ = x \ y’ = y \ x = x_ \ y = y_) \ ! 0 <= x’

(1----) if (0 <= x’) {
(1.1--) while (0 < x’) {
(1.1.1) x’ <- x’ - 1
(1.1.2) y’ <- y’ + 1
(1.1--) }
(1----) } else {
(1?1--) while (x’ < 0) {
(1?1.1) x’ <- x’ + 1
(1?1.2) y’ <- y’ - 1
(1?1--) }
(1----) }

post = y’ = x_ + y_
The case, rcondt and rcondf Tactics

On the first of these goals, we can run the rcondt ("reduce conditional when true") tactic

\[\text{rcondt 1.}\]

which takes the line number (here 1) of the conditional to which the tactic should be applied. This gives us the goals
Type variables: <none>

x_: int
y_: int

Context : {x, y, x’, y’ : int}

pre = (x’ = x \ y’ = y \ x = x_ \ y = y_) \ 0 <= x’

post = 0 <= x’

(which makes us prove that the boolean expression of the conditional is indeed true, after the statements before it (none in this case) are run) and
The case, rcondt and rcondf Tactics

Type variables: <none>

x_: int
y_: int

Context: {x, y, x’, y’ : int}

pre = (x’ = x \ y’ = y \ x = x_ \ y = y_) \ 0 <= x’

(1--) while (0 < x’) {
(1.1) x’ <- x’ - 1
(1.2) y’ <- y’ + 1
(1--) }

post = y’ = x_ + y_

(where the conditional has been replaced by its “then” part).
The other goal generated by the application of case can be solved using the \texttt{rcondf} ("reduce conditional when false") tactic, which makes us prove that the boolean expression of the conditional is false, not true, and handle the reduction to the "else" part of the conditional.
The exfalso Tactic

There are two approaches to solving this goal:

Type variables: <none>

Context : {i : int}

pre = true

(1--) i <- 10
(2--) while (i < 5) {
  (2.1) i <- i + 1
(2--) }

post = i = 10
The exfalso Tactic

If we apply the tactic

  while (i = 10).

this gives us the goals

  Type variables: <none>

  Context: {i : int}

  pre = i = 10 \& i < 5

  (1) i <- i + 1

  post = i = 10

  (showing that the body preserves the invariant when the while loop’s boolean expression is true) and
The exfalso Tactic

Type variables: <none>

Context : \{i : \text{int}\}

pre = true

(1) \ i \ <- \ 10

post = \ i = 10

(which \ EASYCRYPT \ dramatically simplified, making us only prove that the invariant is established—which the auto tactic can solve).
The exfalso Tactic

In the goal

Type variables: <none>

Context : \{i : \text{int}\}

\text{pre} = i = 10 \ \land \ i < 5

(1) \ i \leftarrow i + 1

\text{post} = i = 10

the precondition is inconsistent, and thus we can solve it using the exfalso.

tactic, which makes us prove the goal
The \textit{exfalso} Tactic

Type variables: <none>

\[ \forall \& hr, \ i{hr} = 10 \land i{hr} < 5 \Rightarrow \text{false} \]

(which \textit{smt} can solve).
The *exfalso* Tactic

Alternatively, we can solve the goal

Type variables: <none>

Context : {i : int}

pre = true

(1--) i <- 10
(2--) while (i < 5) {
  (2.1) i <- i + 1
  (2--) }

post = i = 10

using the tactic

   rcondf 2.

(which applies to while loops as well as conditionals). It makes us prove the goals:
The exfalso Tactic

Type variables: <none>

Context : {i : int}

pre = true

(1) i <- 10

post = ! i < 5

(that the code before the while loop makes the while loop’s boolean expression false) and
The exfalso Tactic

Type variables: <none>

Context : {i : int}

pre = true

(1) i <- 10

post = i = 10

(the original goal where the while loop was reduced to nothing). When \texttt{rcondt} is used with while loops, the user must prove that the while loop’s boolean expression is true, after the code before the while loop is executed, and then prove the original goal where the while loop is replaced by its body followed by the while loop (i.e., the result of unfolding the while loop one time).
